We propose an experimental setup that is capable of unambiguously discriminating any pair of linearly independent single photon polarization qubits, about which we don't have any knowledge except that an extra pair of these unknown states are provided as the reference. This setup, which is constructed with optical CNOT gates, weak cross Kerr non-linearities, Bell state analysers and other linear optical elements, transforms the unknown triple photon input states to the corresponding single photon states to be deterministically processed by linear optics circuit. The optimal discrimination of the unknown states is achieved by this setup.

I. INTRODUCTION

When we discriminate a pair of completely unknown quantum states $|\psi_i\rangle$, for $i = 1, 2$, the only possible way is to have copies of these unknown states as the reference, and then we can design the proper measurement that is capable of distinguishing between the inputs, e.g., $|\psi_1\rangle|\psi_2\rangle|\psi_i\rangle$, in which the data states $|\psi_i\rangle$ are appended to the reference copies to form the states with the permutation symmetry. If we require that the incoming unknown data states should be unambiguously discriminated, our device will output three possible results: 1 corresponding to the input being $|\psi_1\rangle$, 2 to that being $|\psi_2\rangle$, and 0 for inconclusiveness. The optimal unambiguous measurement of these symmetric input states has been studied in both the Bayesian [1] and the minimax approaches [2].

Another feature we need to have for such a device is its universality: it will perform optimally for any pair of unknown states. Since the input states are unknown, the only quantity we can use to indicate how well the device works is the average success probability over the Hilbert spaces of all randomly distributed $|\psi_1\rangle$ and $|\psi_2\rangle$, which are discriminated by this single device. For the discrimination of two unknown qubits with one copy of them as the reference, the optimal average success probability can be as large as $1/6$, if these two unknown qubits appear with an equal *a priori* probability [1].

There are ways to improve this optimal average success probability. We can prepare multiple copies of reference and apply different types of measurement, i.e., projection value measure (PVM) and positive operator value measure (POVM) working in different range of *a priori* probability of the inputs, to significantly increase this value, if we follow the Bayesian approach to deal with the problem [3]. For the discriminators to unambiguously identify the averaged unknown input states, the IDP (Ivanovic-

Dieks-Peres) upper bound [4, 5, 6] of success probability in discriminating a pair of known states can be achieved if the copy number of the reference states goes to infinity [7]. To increase the optimal average success probability further, we can use both multiple reference and data copies, so that the device will realize the deterministic discrimination of any pair of unknown states in the limit of infinite reference and data copy numbers together [8].

This type of unknown state discriminators can be of potential value in quantum communication and quantum computing, so it is interesting for us to study their feasible physical implementations. In [9] we propose a pure optical way based on interferometry [10] to deterministically realize the optimal measurements in [1] under the assumption that all the symmetric input states can be prepared as single photon states in multi-rail representation. The quantum circuit to realize the unknown qubits discrimination without achieving the optimal measurement and the possible implementation of its ingredient logic gates in ion traps are studied in [11]. The design of the unitary operators to implement the discrimination of a pair of unknown qubits is also discussed in [12].

In this paper, we design an experimental setup to unambiguously and optimally discriminate the symmetric input states $|\psi_1\rangle|\psi_2\rangle|\psi_i\rangle$ ($i = 1, 2$) prepared with *any* pair of linearly independent unknown single photon polarization qubits. This is a device to process the unknown triple photon input signals, and all the technologies involved have been experimentally realized thus far. After the transformation from the triple photon inputs to single photon signals, only the ancilla of vacuum state will be used in the realization of the optimal POVM the device performs. The rest of the paper is organized as follows: in Sec. II we present the physical basis to realize the optimal measurements designed to discriminate the general unknown qubits, which we intend to realize for the polarization photon systems; in Sec. III we look at the state preparation part of our device, where the triple photon input states are transformed to the single photon states through a combined teleportation protocol, so that they can be deterministically processed by multi-port interferometer; the simplest linear optics circuit to finally

*Electronic address: bhe98@earthlink.net

determine the incoming unknown data qubit is given in Sec. IV; and finally we give some conclusive discussions in the last section.

II. PHYSICAL BASIS TO DISCRIMINATE UNKNOWN OPTICAL QUBITS

We first give a brief review of the optimal measurements for discriminating any pair of unknown states we aim to realize for single photon polarization qubits. The input signals processed by our device are given as follows:

$$\begin{aligned} |\Psi_{1,in}\rangle &= |\psi_1\rangle_1 |\psi_2\rangle_2 |\psi_1\rangle_3 \\ |\Psi_{2,in}\rangle &= |\psi_1\rangle_1 |\psi_2\rangle_2 |\psi_2\rangle_3, \end{aligned} \quad (2.1)$$

where $|\psi_i\rangle = \alpha_i|H\rangle + \beta_i|V\rangle$, for $i = 1, 2$, and H, V are their horizontal and perpendicular polarization modes [13]. Since $|\psi_1\rangle$ and $|\psi_2\rangle$ are linearly independent, there exist different permutation symmetries in these two inputs, and we can therefore design the POVMs, with the elements Π_1 and Π_2 satisfying $\Pi_1|\Psi_2^{in}\rangle = \Pi_2|\Psi_1^{in}\rangle = 0$, to unambiguously discriminate them. In the Bayesian approach [1], the optimal POVM elements for the unambiguous discrimination of the above inputs are

$$\begin{aligned} \Pi_1 &= \frac{2}{3} \left(2 - \sqrt{\frac{\eta_2}{\eta_1}} \right) I_1 \otimes |\Psi_{23}^{as}\rangle \langle \Psi_{23}^{as}|, \\ \Pi_2 &= \frac{2}{3} \left(2 - \sqrt{\frac{\eta_1}{\eta_2}} \right) I_2 \otimes |\Psi_{13}^{as}\rangle \langle \Psi_{13}^{as}|, \end{aligned} \quad (2.2)$$

where $|\Psi_{ij}^{as}\rangle = 1/\sqrt{2}(|H\rangle_i|V\rangle_j - |V\rangle_i|H\rangle_j)$ and I_i the identity operators, if the *a priori* probability η_1 [14] of the data $|\psi_1\rangle$ is in the range of $1/5 \leq \eta_1 \leq 4/5$. For $4/5 \leq \eta_1 \leq 1$, the optimal measurement reduces to the PVM as

$$\begin{aligned} \Pi_1 &= I_1 \otimes |\Psi_{23}^{as}\rangle \langle \Psi_{23}^{as}| \\ \Pi_2 &= 0; \end{aligned} \quad (2.3)$$

and for $0 \leq \eta_1 \leq 4/5$, the index 1 and 2 of the above PVM operators should be interchanged to get the optimal measurement. In the minimax approach without the available *a priori* information of the input data [2], on the other hand, the optimal POVM for discriminating the inputs in Eq. (2.1) is given as

$$\begin{aligned} \Pi_1 &= \frac{2}{3} I_1 \otimes |\Psi_{23}^{as}\rangle \langle \Psi_{23}^{as}|, \\ \Pi_2 &= \frac{2}{3} I_2 \otimes |\Psi_{13}^{as}\rangle \langle \Psi_{13}^{as}|. \end{aligned} \quad (2.4)$$

In both approaches, there is inconclusive measurement result corresponding to the operator $\Pi_0 = I - \Pi_1 - \Pi_2$.

The physical fundamentals to realize the optimal measurements on the unknown input signals are the teleportation of unknown quantum states [15] and the deterministic implementation of a POVM on single photon signals [16]. A teleportation protocol is applied to transform the triple photon input signals in Eq. (2.1) to the corresponding single photon signals running on different tracks:

$$\begin{aligned} |\Psi_{1,in}\rangle &= |\psi_1\rangle_1 |\psi_2\rangle_2 |\psi_1\rangle_3 \\ &= c_1|HHH\rangle + c_2|VHH\rangle + c_3|HHV\rangle + \cdots + c_8|VVV\rangle \\ &\rightarrow c_1|0_A, 0_B, H\rangle + c_2|1_A, 0_B, H\rangle + c_3|0_A, 0_B, V\rangle + \cdots + c_8|1_A, 1_B, V\rangle, \end{aligned} \quad (2.5)$$

where c_i are unknown coefficients, and $0_A, 1_A, 0_B$ and 1_B the symbols related to the which-path degree of freedom of the photon. After some of the input signal's polarization degree of freedom is mapped this way to the which-path degree of freedom, we will obtain a single polarization photon running on 4 different tracks (the total dimensionality of the quantum system is 8) so that any POVM performed on it can be deterministically implemented by linear optics.

To teleport three input qubits in a combined way, we need to have three entangled pairs, e.g.,

$$\begin{aligned} |\Phi_1^+\rangle &= \frac{1}{\sqrt{2}}(|H\rangle|H\rangle + |V\rangle|V\rangle), \\ |\Phi_2^+\rangle &= \frac{1}{\sqrt{2}}(|H\rangle|0_A\rangle + |V\rangle|1_A\rangle), \\ |\Phi_3^+\rangle &= \frac{1}{\sqrt{2}}(|H\rangle|0_B\rangle + |V\rangle|1_B\rangle). \end{aligned} \quad (2.6)$$

We here define the four Bell states as follows:

$$\begin{aligned} |\Phi^\pm\rangle &\equiv \frac{1}{\sqrt{2}}(|0\rangle|0\rangle \pm |1\rangle|1\rangle), \\ |\Psi^\pm\rangle &\equiv \frac{1}{\sqrt{2}}(|0\rangle|1\rangle \pm |1\rangle|0\rangle), \end{aligned} \quad (2.7)$$

where 0 can be $H, 0_A, 0_B$, etc, and 1 can be $V, 1_A, 1_B$, etc. Two of the states in Eq. (2.6) involve both polarization and which-path degrees of freedom. How to effectively produce them is what we will discuss in the next section.

III. CONVERSION TO SINGLE PHOTON SIGNAL

In this section, we give a rather detailed description of a circuit to map the triple photon input signals to the

FIG. 1: (Color online) The quantum non-demolition detection to separate even parity $\{|H\rangle_B|H\rangle_C, |V\rangle_B|V\rangle_C\}$ from the odd parity $\{|H\rangle_B|V\rangle_C, |V\rangle_B|H\rangle_C\}$ states. Through one of the weak non-linear cross-Kerr, the laser probe initially in the coherent states $|\alpha\rangle$ will evolve to $|\alpha e^{i\theta}\rangle$ or $|\alpha e^{-i\theta}\rangle$, if the single photon is present too. By a homodyne detection $|\alpha e^{\pm i\theta}\rangle$ resulting from the odd parity can be discriminated from $|\alpha\rangle$ from the even. We classically feedforward the detection result to the switch, S , to direct the odd parity component to the track B_1 and the even parity component to the track B_2 . On B_1 the odd parity is restored to the even by the bit flip and the necessary phase shifters. We use a fictitious *controlling action qubit*, $\alpha|0_A\rangle + \beta|1_A\rangle$, acting on the track B photon component to describe the combined action of the CNOT gate and this QND.

corresponding single photon signals as in Eq. (2.5).

To begin with, we look at the transformation of a double photon polarization state $|\Psi_{in}\rangle = |\psi_1\rangle_1|\psi_2\rangle_2$, where $|\psi_i\rangle = \alpha_i|H\rangle + \beta_i|V\rangle$, to the corresponding single photon state by a combined teleportation procedure. We use two extra photon sources $1/\sqrt{2}(|H\rangle_A + |V\rangle_A)$ and $1/\sqrt{2}(|H\rangle_B|H\rangle_C + |V\rangle_B|V\rangle_C)$, and let the first photon on track A control the part B of the second entangled photon pair through a CNOT gate taking the following action:

$$U_{CNOT} = (|H\rangle_A\langle H| \otimes I_B + |V\rangle_A\langle V| \otimes \sigma_{x,B}) \otimes I_C. \quad (3.1)$$

The above equation means that there will be no action on track B if the photon component on track A is in the state of $|H\rangle$ and there will be a bit flip $\sigma_{x,B}$ of $\{H, V\}$ on track B if that photon component is in $|V\rangle$. After the joint unitary map U_{CNOT} , the total state on the track A , B and C will be as follows (here we neglect the common factors for brevity):

$$\begin{aligned} & U_{CNOT}(|H\rangle_A + |V\rangle_A)(|H\rangle_B|H\rangle_C + |V\rangle_B|V\rangle_C) \\ &= |H\rangle_A|H\rangle_B|H\rangle_C + |H\rangle_A|V\rangle_B|V\rangle_C + |V\rangle_A|V\rangle_B|H\rangle_C + |V\rangle_A|H\rangle_B|V\rangle_C. \end{aligned} \quad (3.2)$$

This type of non-destructive optical CNOT gate has been experimentally demonstrated [17] and, theoretically, a CNOT gate for two independent single photon polarization qubits can be realized near deterministically [18].

The output state of the CNOT gate in Eq. (3.2) is divided into two sets for part B and C : the even parity $\{|H\rangle_B|H\rangle_C, |V\rangle_B|V\rangle_C\}$ and the odd parity $\{|H\rangle_B|V\rangle_C, |V\rangle_B|H\rangle_C\}$, and they can be discriminated near deterministically by a polarization parity quantum non-demolition detection (QND) [18]. The setup to realize this QND includes a laser probe initially in a coherent state $|\alpha\rangle_p$ and the cross-Kerr nonlinearities, which have a Hamiltonian $H = \hbar\chi a_s^\dagger a_s a_p^\dagger a_p$, where the signal (probe) mode has the creation and destruction operators given by $a_s^\dagger, a_s(a_p^\dagger, a_p)$ and χ the strength of nonlinearity which can be weak. Through the interaction in the weak non-linear cross-Kerr in Fig. 1, the photon states on track B ,

C and the probe evolve together to $|\psi_T\rangle \sim (|H\rangle_B|H\rangle_C + |V\rangle_B|V\rangle_C)|\alpha\rangle_p + |H\rangle_B|V\rangle_C|\alpha e^{i\theta}\rangle_p + |V\rangle_B|H\rangle_C|\alpha e^{-i\theta}\rangle_p$, where $\theta = \chi t$ with t being the interaction time. $|\alpha\rangle$ and $|\alpha e^{\pm i\theta}\rangle$ can be distinguished between each other by a homodyne-heterodyne measurement on the probe.

Then we classically feedforward two actions to the output on track B : if the detection result is $|\alpha e^{\pm i\theta}\rangle$, we let the photon component on track B go to path B_1 and denote the action 0_A (the index A means the control from track A photon component); and if the result is $|\alpha\rangle$, the photon component on track B is redirected to track B_2 with an action named 1_A . A bit flip (plus the phase shift redressing due to the QND) on B_1 track is performed to restore the odd parity of the photon components on track B and C to the even parity, i.e., $|HV\rangle, |VH\rangle \rightarrow |HH\rangle, |VV\rangle$. As the result, we obtain a state,

$$\begin{aligned}
|\psi^{ent}\rangle &\sim |H\rangle_A |H\rangle_{B_1,0_A} |H\rangle_C + |H\rangle_A |V\rangle_{B_1,0_A} |V\rangle_C + |V\rangle_A |H\rangle_{B_2,1_A} |H\rangle_C + |V\rangle_A |V\rangle_{B_2,1_A} |V\rangle_C \\
&= (|H\rangle_A |0_A\rangle + |V\rangle_A |1_A\rangle)(|H\rangle_B |H\rangle_C + |V\rangle_B |V\rangle_C),
\end{aligned} \tag{3.3}$$

which can be factorized into the product of two entangled states. $|0_A\rangle$ and $|1_A\rangle$ are defined as two *controlling switch actions* on the track B photon component from the photon component on track A. These two fictitious quantum states describe the effective action of track B photon component to go to different paths B_1 and B_2 under the control:

$$|0_A\rangle |H\rangle_B \equiv |H\rangle_{B_1,0_A}, \quad |1_A\rangle |H\rangle_B \equiv |H\rangle_{B_2,1_A},$$

$$|0_A\rangle |V\rangle_B \equiv |V\rangle_{B_1,0_A}, \quad |1_A\rangle |V\rangle_B \equiv |V\rangle_{B_2,1_A}. \tag{3.4}$$

It is feasible, therefore, to use these two entangle states to teleport $|\Psi_{in}\rangle = |\psi_1\rangle_1 |\psi_2\rangle_2$ to a single photon polarization state:

$$\begin{aligned}
&|\psi_1\rangle_1 (|H\rangle_A |0_A\rangle + |V\rangle_A |1_A\rangle) |\psi_2\rangle_2 (|H\rangle_B |H\rangle_C + |V\rangle_B |V\rangle_C) \\
&\sim (|\Phi^+\rangle_{1,A} |\psi_1\rangle_{A_{Ct}} + |\Psi^+\rangle_{1,A} (\sigma_{x,A_{Ct}} |\psi_1\rangle_{A_{Ct}}) + |\Psi^-\rangle_{1,A} (-i\sigma_{y,A_{Ct}} |\psi_1\rangle_{A_{Ct}}) + |\Phi^-\rangle_{1,A} (\sigma_{z,A_{Ct}} |\psi_1\rangle_{A_{Ct}})) \\
&\times (|\Phi^+\rangle_{2,C} |\psi_2\rangle_B + |\Psi^+\rangle_{2,C} (\sigma_{x,B} |\psi_2\rangle_B) + |\Psi^-\rangle_{2,C} (-i\sigma_{y,B} |\psi_2\rangle_B) + |\Phi^-\rangle_{2,C} (\sigma_{z,B} |\psi_2\rangle_B)),
\end{aligned} \tag{3.5}$$

where the *controlling action qubit* is defined as $|\psi_1\rangle_{A_{Ct}} = \alpha_1 |0_A\rangle + \beta_1 |1_A\rangle$, and σ_x , σ_y and σ_z the Pauli matrices. With a final restoring unitary transformation U_{rest} on both the tracks B_1 , B_2 and the polarization modes H , V according to the information fed forwarded after the Bell

state analysis on track 1, A and 2, C, respectively, we will obtain a single photon polarization state running on track B_1 and B_2 (the total dimensionality of the outputs is 4 as the inputs):

$$\begin{aligned}
|\Psi_{out}\rangle &= |\psi_1\rangle_{A_{Ct}} |\psi_2\rangle = (\alpha_1 |0_A\rangle + \beta_1 |1_A\rangle) (\alpha_2 |H\rangle_B + \beta_2 |V\rangle_B) \\
&= \alpha_1 \alpha_2 |H\rangle_{B_1,0_A} + \alpha_1 \beta_2 |V\rangle_{B_1,0_A} + \beta_1 \alpha_2 |H\rangle_{B_2,1_A} + \beta_1 \beta_2 |V\rangle_{B_2,1_A}.
\end{aligned} \tag{3.6}$$

The complete (and close to deterministic) Bell state analysis setups can be found in [19, 20, 21], and also in [22] a practical method for teleporting optical qubits is given. These experimental schemes can be modified to realize the operations in our setup. The whole scheme to realize the transformation from double to single photon states is given in Fig. 2.

So far we have put together all necessary ingredients of a circuit to transform the triple photon inputs in Eq.

(2.1) to the corresponding single photon states. To teleport the triple photon inputs to the corresponding single photon states, we just need to continue the above procedure before the Bell state analysis by adding one more single photon source, $1/\sqrt{2}(|H\rangle_D + |V\rangle_D)$, and two more CNOT gates and parity QNDs. We use a 50-50 beam splitter to split the second single photon into two different paths:

$$|H\rangle_D + |V\rangle_D \rightarrow |H\rangle_{D_1} + |V\rangle_{D_1} + |H\rangle_{D_2} + |V\rangle_{D_2}, \tag{3.7}$$

FIG. 2: (Color online) The scheme to transform a two-photon state, $|\Psi_{in}\rangle = |\psi_1\rangle|\psi_2\rangle$, to a single photon polarization state running on two different tracks, $|\Psi_{out}\rangle$. We use a BBO to generate an entangled pair $1/\sqrt{2}(|H\rangle_B|H\rangle_C + |V\rangle_B|V\rangle_C)$ on track B and C, and put a single photon $1/\sqrt{2}(|H\rangle_A + |V\rangle_A)$ on track A. The CNOT gate can be a modified version of the cited, and the QND unit is shown in Fig. 1. The results of two Bell state analysis are sent through the classical channels to where the restoration unitary map U_{rest} is performed. U_{rest} is chosen from a finite set of operations.

FIG. 3: (Color online) The scheme to teleport any symmetric unknown three-photon input state $|\psi_1\rangle|\psi_2\rangle|\psi_i\rangle$, for $i = 1, 2$, to the corresponding single photon state. One more single photon source is used on track D, and it is split by a 50-50 beam splitter BS_1 (and the necessary phase shifters) into two paths to control the respective photon components. Another identical beam splitter BS_2 merges the photon components on track D_1 and D_2 to a single path again.

and the photon components running on D_1 (D_2) track controls the photon component on B_1 (B_2) track through an optical CNOT gate. Then, performing the polarization parity QNDs on track B_1 , C and B_2 , C , respectively, and the necessary bit flips and phase redressing, we will

separate the photon components on B_1 and B_2 to those on 4 tracks $B_{1,1}$, $B_{1,2}$, $B_{2,1}$ and $B_{2,2}$, and thus obtain the output state which can be factorized into the product of three entangled states (similar to the state in Eq. (3.3)). We are now able to teleport 3 unknown qubits together

to a single photon polarization state running on 4 different tracks. The complete scheme of the teleportation of the triple-qubit to a single photon state is shown in Fig. 3.

IV. OPTIMAL POVM IMPLEMENTATION CIRCUIT

The circuit in Fig. 3 generates the following single photon states as the inputs of the POVM modules to

$$\begin{aligned}
 |\Psi'_{i,in}\rangle &= |\Psi_{i,out}\rangle = |\psi_1\rangle_{D_{Ct}} |\psi_2\rangle_{A_{Ct}} |\psi_i\rangle_B \\
 &= (\alpha_1|0_D\rangle + \beta_1|1_D\rangle)(\alpha_2|0_A\rangle + \beta_2|1_A\rangle)(\alpha_i|H\rangle_B + \beta_i|V\rangle_B) \\
 &= \alpha_1\alpha_2\alpha_i|0_D, 0_A, H_B\rangle + \alpha_1\alpha_2\beta_i|0_D, 0_A, V_B\rangle + \alpha_1\beta_2\alpha_i|0_D, 1_A, H_B\rangle + \alpha_1\beta_2\beta_i|0_D, 1_A, V_B\rangle \\
 &\quad + \beta_1\alpha_2\alpha_i|1_D, 0_A, H_B\rangle + \beta_1\alpha_2\beta_i|1_D, 0_A, V_B\rangle + \beta_1\beta_2\alpha_i|1_D, 1_A, H_B\rangle + \beta_1\beta_2\beta_i|1_D, 1_A, V_B\rangle \\
 &= \alpha_1\alpha_2\alpha_i|H\rangle_{B_{1,1}} + \alpha_1\alpha_2\beta_i|V\rangle_{B_{1,1}} + \alpha_1\beta_2\alpha_i|H\rangle_{B_{2,1}} + \alpha_1\beta_2\beta_i|V\rangle_{B_{2,1}} \\
 &\quad + \beta_1\alpha_2\alpha_i|H\rangle_{B_{1,2}} + \beta_1\alpha_2\beta_i|V\rangle_{B_{1,2}} + \beta_1\beta_2\alpha_i|H\rangle_{B_{2,2}} + \beta_1\beta_2\beta_i|V\rangle_{B_{2,2}},
 \end{aligned} \tag{4.1}$$

FIG. 4: (Color online) The unitary transformation module constructed with beam splitters (dark square) and phase shifters (white square). Any unitary operator represented by an $N \times N$ matrix can be implemented by an $N \times N$ ports module of this kind with the maximum $N(N-1)/2$ of beam splitters [10].

where the actions defined in Eq. (3.4) are used in the notation. With 4 polarization beam splitters (PBS) we can thus obtain the multi-rail single photon signal states running on 8 tracks. Any POVM with n elements Π_i , for $i = 1, \dots, n$, on such single photon states can be deterministically implemented with at most $3n-2$ linear optics modules shown in Fig. 4 [16].

The POVM for unambiguously discriminating these states satisfies more condition, $\Pi_1|\Psi'_{2,in}\rangle = \Pi_2|\Psi'_{1,in}\rangle = 0$, so we can use a linear optics scheme, which requires fewer and much simpler modules, to realize the unambiguous discrimination of $|\Psi'_{1,in}\rangle$ and $|\Psi'_{2,in}\rangle$. Such a scheme works with the following unitary map [9],

$$U_{module} = \begin{pmatrix} (I - \Pi_0)^{\frac{1}{2}} & -\Pi_0^{\frac{1}{2}} \\ \Pi_0^{\frac{1}{2}} & (I - \Pi_0)^{\frac{1}{2}} \end{pmatrix}, \tag{4.2}$$

discriminate the data $|\psi_1\rangle$ and $|\psi_2\rangle$:

which is realizable by one 16×16 -port module shown in Fig. 4. This module transforms the signals embed in a larger space of the double of the signal space dimension, $(|\Psi'_{i,in}\rangle, \mathbf{0})^T$, to the components in two orthogonal output subspaces:

$$U_{module} \begin{pmatrix} |\Psi'_{i,in}\rangle \\ \mathbf{0} \end{pmatrix} = \begin{pmatrix} (I - \Pi_0)^{\frac{1}{2}} |\Psi'_{i,in}\rangle \\ \Pi_0^{\frac{1}{2}} |\Psi'_{i,in}\rangle \end{pmatrix}. \tag{4.3}$$

The component $(I - \Pi_0)^{\frac{1}{2}} |\Psi'_{i,in}\rangle$ corresponds to the success of the measurement with a probability $P = \langle \Psi'_{i,in} | I - \Pi_0 | \Psi'_{i,in} \rangle = \langle \Psi'_{i,in} | \Pi_i | \Psi'_{i,in} \rangle$, and the component $\Pi_0^{\frac{1}{2}} |\Psi'_{i,in}\rangle$ to the inconclusive result, which occurs with a probability $Q = \langle \Psi'_{i,in} | \Pi_0 | \Psi'_{i,in} \rangle$. It is easy to verify that $|\Psi'_{1,in}\rangle$ and $|\Psi'_{2,in}\rangle$ are mapped to distinguishable orthogonal states in the first subspace, since $\langle \Psi'_{1,in} | I - \Pi_0 | \Psi'_{2,in} \rangle = 0$.

The linear optics circuit to perform U_{module} can be simplified further. We first decompose the inputs in Eq. (4.1) into the components in the orthogonal subspaces $\mathcal{H}_1 = \{|0_D, 0_A, V_B\rangle, |0_D, 1_A, H_B\rangle, |1_D, 0_A, H_B\rangle\}$, $\mathcal{H}_2 = \{|1_D, 0_A, V_B\rangle, |0_D, 1_A, V_B\rangle, |1_D, 1_A, H_B\rangle\}$, $\mathcal{H}_3 = \{|0_D, 0_A, H_B\rangle\}$ and $\mathcal{H}_4 = \{|1_D, 1_A, V_B\rangle\}$, respectively. We introduce a unitary map V_1 ,

$$\begin{aligned}
|\Phi_1\rangle &= \sqrt{\frac{1}{2}}(|0_D, 0_A, V_B\rangle - |0_D, 1_A, H_B\rangle) \\
|\Phi_2\rangle &= \sqrt{\frac{1}{6}}(|0_D, 0_A, V_B\rangle + |0_D, 1_A, H_B\rangle) - \sqrt{\frac{2}{3}}|1_D, 0_A, H_B\rangle \\
|\Phi_3\rangle &= \sqrt{\frac{1}{3}}(|0_D, 0_A, V_B\rangle + |0_D, 1_A, H_B\rangle + |1_D, 0_A, H_B\rangle),
\end{aligned} \tag{4.4}$$

in $\mathcal{H}_1$, and another unitary map V_2 ,

$$\begin{aligned}
|\Phi'_1\rangle &= \sqrt{\frac{1}{2}}(|1_D, 0_A, V_B\rangle - |1_D, 1_A, H_B\rangle) \\
|\Phi'_2\rangle &= \sqrt{\frac{1}{6}}(|1_D, 0_A, V_B\rangle + |1_D, 1_A, H_B\rangle) - \sqrt{\frac{2}{3}}|1_D, 0_A, V_B\rangle \\
|\Phi'_3\rangle &= \sqrt{\frac{1}{3}}(|1_D, 0_A, V_B\rangle + |1_D, 1_A, H_B\rangle + |0_D, 1_A, V_B\rangle)
\end{aligned} \tag{4.5}$$

in $\mathcal{H}_2$, respectively. These two unitary maps on the modes of the relevant tracks correspond to two simple and identical 3×3 -port modules processing the relevant components of the input signals. In the subspaces $\mathcal{H}'_1 = \{|\Phi_1\rangle, |\Phi_2\rangle\}$ and $\mathcal{H}'_2 = \{|\Phi'_1\rangle, |\Phi'_2\rangle\}$, Π_0 of the optimal POVM is given as a 2×2 matrix [1]:

$$\Pi_0^{(i)} = \begin{pmatrix} -\frac{2}{3}(1 - \sqrt{\frac{\eta_1}{\eta_2}} - \sqrt{\frac{\eta_2}{\eta_1}}) & -\frac{\sqrt{3}}{6}(2 - \sqrt{\frac{\eta_1}{\eta_2}}) \\ -\frac{\sqrt{3}}{6}(2 - \sqrt{\frac{\eta_1}{\eta_2}}) & \frac{2}{3}\sqrt{\frac{\eta_1}{\eta_2}} \end{pmatrix}, \tag{4.6}$$

for $i = 1, 2$, and the total Π_0 is the direct sum,

$$\Pi_0 = \Pi_0^{(1)} \oplus \Pi_0^{(2)} \oplus I. \tag{4.7}$$

Therefore, the signal components outside $\mathcal{H}'_1$ and $\mathcal{H}'_2$ only contribute to the inconclusive results, and we only need to process the signal components in these two subspaces.

For the *a priori* probabilities $\eta_1 = \eta_2 = 1/2$, i.e., the most difficult situation to discriminate the input data,

as well as the optimal POVM obtained in the minimax approach [2], the operator $\Pi_0^{(1)}$ and $\Pi_0^{(2)}$ are therefore reduced to

$$\Pi_0^{(1)} = \Pi_0^{(2)} = \begin{pmatrix} \frac{2}{3} & -\frac{\sqrt{3}}{6} \\ -\frac{\sqrt{3}}{6} & \frac{2}{3} \end{pmatrix}. \tag{4.8}$$

The unitary transformations in Eq. (4.2) constructed by these two non-unitary operators are, respectively, implemented by two identical circuits consisting of only 3 beam splitters, one of which performs the unitary map,

$$U_{i,1} = \begin{pmatrix} -\frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \end{pmatrix}, \tag{4.9}$$

which diagonalizes $\Pi_0^{(1)}$ and $\Pi_0^{(2)}$, and the other two of which perform the unitary map in the extended space,

$$U_{i,2} = \begin{pmatrix} \sqrt{\frac{1}{3} - \frac{\sqrt{3}}{6}} & -\sqrt{\frac{2}{3} + \frac{\sqrt{3}}{6}} & \\ \sqrt{\frac{1}{3} + \frac{\sqrt{3}}{6}} & -\sqrt{\frac{2}{3} - \frac{\sqrt{3}}{6}} & \\ \sqrt{\frac{2}{3} + \frac{\sqrt{3}}{6}} & \sqrt{\frac{1}{3} - \frac{\sqrt{3}}{6}} & \sqrt{\frac{1}{3} + \frac{\sqrt{3}}{6}} \end{pmatrix}. \tag{4.10}$$

Through all these unitary transformations the different input signal components from $|\Psi'_{1,in}\rangle$ and $|\Psi'_{2,in}\rangle$, re-

spectively, have been mapped to the orthogonal states.

FIG. 5: (Color online) The layout of the optimal POVM implementation. The input $|\Psi'_{in}\rangle$ is the output $|\Psi_{out}\rangle$ in Fig. 3. The polarization beam splitters (PBS) separate the input into the 8 dimensional single photon state in multi-rail representation. The V_i are 3×3 -port modules, and U_i 4×4 -port modules with two input ports black. Only 4 photon detectors are required to place on the terminals where the useful information is output. At all other terminals (2 of the PBS, 2 of V_i modules and 4 of U_i modules), there are only useless signals contributing to the inconclusiveness. We can set the output in such a pattern: if the detector C_1 or C_3 clicks, we conclude that the unknown input is $|\psi_1\rangle$; and if C_2 or C_4 clicks, the input data must be $|\psi_2\rangle$. From each counter, we detect the photon with a probability $1/12$, if the data $|\psi_1\rangle$ and $|\psi_2\rangle$ occur with the same *a priori* probability.

Adding one more 50-50 beam splitter to separate the signals from the different inputs, we realize the target to discriminate the data input: the input data is determined to be $|\psi_1\rangle$ if the output photon is recorded by one single photon detector and $|\psi_2\rangle$ if the output photon is recorded by the other. In Fig. 5 we use U_i to represent a whole package of these unitary maps including $U_{i,1}$ and $U_{i,2}$.

By a straightforward calculation considering Eq. (4.4)-(4.5), (4.9) and (4.10), we see that in one of the photon detectors in Fig. 5 there is an average probability of $1/12$ to detect the photon. With the detection of the photon, we can draw the conclusion about which the input data is. Adding together the contribution of another photon detector placed at one terminal of the other U_i module, we obtain the optimal average success probability $1/6$ in

the discrimination of a pair of unknown qubits [1]. The layout of the optimal POVM implementation is given in Fig. 5.

V. SUMMARY AND DISCUSSION

We have constructed a setup to unambiguously and optimally distinguish between any pair of linearly independent single photon polarization qubits, which are completely unknown to us. This proposed experimental setup applies the state-of-the-art technologies to process quantum information, e.g., the non-destructive optical CNOT gates, the complete and near deterministic Bell states analysis including the teleportation of optical qubit, etc., which have been experimentally realized [17, 19, 20, 21, 22]. Neglecting the possible error in the operation, the optimal discrimination of any pair of unknown optical qubits can be deterministically performed with this device. The future advance in these technologies will make such a device more reliable and less costly.

In principle, we can also generalize the setup to a device that works with multiple reference or data copies, which will increase the success probability in discriminating the unknown data [3], or a device that discriminates more than two unknown states [2]. This can be done by teleporting more *controlling switch action states*, but the restriction is the cost of the above mentioned experimental facilities. Another generalization is a setup that unambiguously and optimally discriminates any pair of unknown d-level quantum systems, i.e., *qudits*. Due to the lack of knowledge about the quantum circuits of the *qudits*, it seems that so far there has been no available experimental facility to directly discriminate two unknown *qudits* unless we first transform them, together with the reference copies, to qubits with a certain possibility. These interesting problems, as well as the experimental implementation of the setup we propose in this paper, are worth further study.

- [13] We can as well use the slightly modified devices to deal

- with the unknown qubits in other forms of basis, e.g., the circular polarization states $|\psi_i\rangle = \alpha_i|L\rangle + \beta_i|R\rangle$, where $|L\rangle = (|H\rangle + i|V\rangle)/\sqrt{2}$, $|R\rangle = (|H\rangle - i|V\rangle)/\sqrt{2}$.
- [14] Here we suppose the *a priori* probabilities of the data always satisfy $\eta_1 + \eta_2 = 1$, i.e., there is no failure in the preparation of the input data.
